GUIDELINES

Multiprofessional guidelines for the management of the patient with primary cutaneous squamous cell carcinoma

Summary
These guidelines for management of primary cutaneous squamous cell carcinoma present evidence-based guidance for treatment, with identification of the strength of evidence available at the time of preparation of the guidelines, and a brief overview of epidemiological aspects, diagnosis and investigation.

Disclaimer
These guidelines, prepared on behalf of the British Association of Dermatologists, the British Association of Plastic Surgeons and in consultation with members of the Faculty of Clinical Oncology of the Royal College of Radiologists, reflect the best published data available at the time the report was prepared. Caution should be exercised in interpreting the data; the results of future studies may require alteration of the conclusions or recommendations in this report. It may be necessary or even desirable to depart from the guidelines in the interests of specific patients and special circumstances. Just as adherence to the guidelines may not constitute defence against a claim of negligence, so deviation from them should not be necessarily deemed negligent.

Definition
Primary cutaneous squamous cell carcinoma (SCC) is a malignant tumour that may arise from the keratinizing cells of the epidermis or its appendages. It is locally invasive and has the potential to metastasize to other organs of the body. These guidelines are confined to the treatment of SCC of the skin and the vermilion border of the lip, and exclude SCC of the penis, vulva and anus, SCC in situ (Bowen’s disease), SCC arising from mucous membranes, and keratoa- canthoma.

Incidence, aetiology and prevention
SCC is the second most common skin cancer and, in many countries, its incidence is rising.1–5 Its occurrence is usually related to chronic ultraviolet light exposure and is therefore especially common in the sun-damaged skin of fair-skinned individuals, in albinos and in those with xeroderma pigmentosum. It may develop de novo, as a result of previous exposure to ionizing radiation or arsenic, within chronic wounds, scars, burns, ulcers or sinus tracts, and from pre-existing lesions such as Bowen’s disease (‘intraepidermal SCC’).6–14 Individuals with impaired immune function, for example those receiving immunosuppressive drugs following allogeneic organ transplantation or those with lymphoma or leukaemia, are at increased risk of this tumour; some SCCs are associated with human papillomavirus infection.15–23 There is good evidence linking SCCs with chronic actinic damage and to support the use of sun avoidance, protective clothing and effective sunblocks in the prevention of actinic keratoses and SCCs; this is particularly important for patients receiving long-term immunosuppressive medication.24–27

These guidelines were commissioned by the British Association of Dermatologists Therapy Guidelines and Audit subcommittee. Members of the committee are: N.H.Cox (Chairman), A.V.Anstey, C.B.Bunker, M.J.D.Goodfield, A.S.Highet, D.Mehta, R.H.Meyrick Thomas, J.K.Schofield.

Clinical presentation

SCC usually presents as an indurated nodular keratinizing or crusted tumour that may ulcerate, or it may present as an ulcer without evidence of keratinization.

Diagnosis

The diagnosis is established histologically. The histology report should include the following: pathological pattern (e.g. ‘adenoid type’) cell morphology (e.g. ‘spindle cell SCC’), degree of differentiation (‘well differentiated’ or ‘poorly differentiated’), histological grade (as described by Broders, Appendix 2), depth (thickness in mm), the level of dermal invasion (as Clark’s levels, excluding layers of surface keratin), and the presence or absence of perineural, vascular or lymphatic invasion. The margins of the excised tissue should be stained prior to tissue preparation to allow their identification histologically and comment should be made on the lateral and deep margins of excision.28–40

Prognosis

The accumulated experience of treating cutaneous SCC by various methods has allowed some generalizations to be made about prognosis based on the original lesion. Factors that influence metastatic potential include anatomical site, size, rate of growth, aetiology, degree of histological differentiation and host immunosuppression. These details are frequently omitted from reported series of treated SCC and the conclusions of such series must therefore be interpreted with caution. Patient referral patterns may influence local experience of this condition, and series reported from office practices tend to suggest a more favourable prognosis than cases reported from hospital and tertiary centres.41–48

Factors affecting metastatic potential of cutaneous squamous cell carcinoma (SCC)

Site

Tumour location influences prognosis: sites are listed in order of increasing metastatic potential.10,41,49–52

1 SCC arising at sun-exposed sites excluding lip and ear.
2 SCC of the ear.
3 SCC of the lip.
4 Tumours arising in non-sun-exposed sites (e.g. perineum, sacrum, sole of foot).
5 SCC arising in areas of radiation or thermal injury, chronic draining sinuses, chronic ulcers, chronic inflammation or Bowen’s disease.

Size: diameter

Tumours greater than 2 cm in diameter are twice as likely to recur locally (15·2% vs. 7·4%), and three times as likely to metastasize (30·3% vs. 9·1%) as smaller tumours.41

Size: depth

Tumours greater than 4 mm in depth (excluding surface layers of keratin) or extending down to the subcutaneous tissue (Clark level V) are more likely to recur and metastasize (metastatic rate 45·7%) compared with thinner tumours.29,35,41 Recurrence and metastases are less likely in tumours confined to the upper half of the dermis and less than 4 mm in depth (metastatic rate 6·7%).31,32,35,41

Histological differentiation

Poorly differentiated tumours (i.e. those of Broders’ grades 3 and 4: Appendix 2) have a poorer prognosis, with more than double the local recurrence rate and triple the metastatic rate of better differentiated SCC.33,34,41 Tumours with perineural involvement are more likely to recur and to metastasize.39,53 It seems logical that lymphatic or vascular invasion might imply a poor prognosis, but there is no evidence to support this as an independent risk factor.

Host immunosuppression

Tumours arising in patients who are immunosuppressed have a poorer prognosis. Host cellular immune response may be important both in determining the local invasiveness of SCC and the host’s response to metastases.22,23,28

Previous treatment and treatment modality

The risk of local recurrence depends upon the treatment modality. Locally recurrent disease itself is a risk factor for metastatic disease. Local recurrence rates are
considerably less with Mohs’ micrographic surgery than with any other treatment modality.41,50–52,54,55

Treatment

In interpreting and applying guidelines for treatment of SCC, three important points should be noted:
• There is a lack of randomized controlled trials (RCTs) for the treatment of primary cutaneous SCC.
• There is widely varying malignant behaviour in those tumours that fall within the histological diagnostic category of ‘primary cutaneous SCC’.
• There are varied experiences among the different specialists treating these tumours; these are determined by referral patterns and interests. Plastic and maxillofacial surgeons may encounter predominantly high-risk, aggressive tumours, whereas dermatologists may deal predominantly with smaller and less aggressive lesions.

However, there are three main factors that influence treatment, which are:
• the need for complete removal or treatment of the primary tumour;
• the possible presence of local ‘in transit’ metastases;
• the tendency of metastases to spread by lymphatics to lymph nodes.

The majority of SCCs are low risk and amenable to various forms of treatment, but it is essential to identify the significant proportion that are high-risk. These may be best managed by a multiprofessional team with experience of treating the most malignant tumours.42,43,45,48,56–59

The goal of treatment is complete (preferably histologically confirmed) removal or destruction of the primary tumour and of any metastases. In order to achieve this the margins of the tumour must be identified. The gold standard for identification of tumour margins is histological assessment, but most treatments rely on clinical judgement. It must be recognized that this is not always an accurate predictor of tumour extent, particularly where the margins of the tumour are ill-defined.40,60–63

SCC may give rise to local metastases, which are discontinuous with the primary tumour. Such ‘in-transit’ metastases may be removed by wide surgical excision or destroyed by irradiation of a wide field around the primary lesion. Small margins may not remove metastases in the vicinity of the primary tumour. Locally recurrent tumour may arise either due to failure to treat the primary continuous body of tumour, or from local metastases.28,32,42,43,45,54,56,64,65

SCC usually spreads to local lymph nodes and clinically enlarged nodes should be examined histologically (for example by fine needle aspiration or excisional biopsy). Tumour-positive lymph nodes are usually managed by regional node dissection, but detailed discussion of the management of metastatic disease is beyond the scope of these guidelines.49,66–69

In the absence of clinically enlarged nodes, techniques such as high resolution ultrasound-guided fine needle aspiration cytology may be useful in evaluating regional lymph nodes in patients with high risk tumours.70–73 The role of sentinel lymph node biopsy has not been established.

Although there are many large series in which long-term outcome after treatment for cutaneous SCC has been reported (comprehensively summarized in Rowe et al.41), there are no large prospective randomized studies in which different treatments for this tumour have been compared.42,43,54,57,64,65

Guidelines for patient treatment

Conclusions from population-based studies do not necessarily indicate the best treatment for an individual patient. In particular, when choosing a treatment modality it is important to be aware of the factors that may influence success. Curettage and cautery, cryosurgery, and to a lesser degree radiotherapy, are all techniques in which the outcome depends on the experience of the physician. Although the same could be said of surgical excision and Mohs’ micrographic surgery, these two modalities provide tissue for histological examination that allows the pathologist to assess the adequacy of treatment and for the physician to undertake further surgery if necessary. For this reason, where feasible, surgical excision (including Mohs’ micrographic surgery where appropriate) should be regarded as the treatment of first choice for cutaneous SCC. The other techniques can yield excellent results in experienced hands, but the quality of treatment cannot be assured or audited contemporaneously by a third party.28,41,46,61,62,67,69,74,77–79

Surgical excision

Surgical excision is the treatment of choice for the majority of cutaneous SCC. It allows full characterization of the tumour and a guide to the adequacy of treatment through histological examination of the margins of the excised tissue.32,41
When undertaking surgical excision a margin of normal skin is excised from around the tumour. For clinically well-defined, low risk tumours less than 2 cm in diameter, surgical excision with a minimum 4-mm margin around the tumour border is appropriate and would be expected to completely remove the primary tumour mass in 95% of cases (Strength of Recommendation A, Quality of Evidence II-iii). Narrower margins of excision are more likely to leave residual tumour. In order to maintain the same degree of confidence of adequate excision, larger tumours, high risk tumours of Broders’ grade 2, 3 or 4, tumours extending into the subcutaneous tissue and those in high-risk locations (ear, lip, scalp, eyelids, nose) should be removed with a wider margin (6 mm or more) and the tissue margins examined histologically, or with Mohs’ micrographic surgery.

It is only meaningful to consider such margins when the peripheral boundary of the tumour appears clinically well-defined. The concept of a ‘surgical margin’ (i.e. normal-appearing tissue around the tumour) is based upon an assumption that the clinically visible margin of the tumour bears a predictable relationship to the true extent of the tumour, and that excision of a margin of clinically normal-appearing tissue around the tumour will encompass any microscopic tumour extension. The wider the surgical margin, the greater the likelihood that all tumour will be removed. Large tumours have greater microscopic tumour extension and should be removed with a wider margin. This concept is equally valid for non-surgical treatments such as radiotherapy and cryotherapy in which a margin of clinically normal-appearing tissue is treated around the tumour. Mohs’ micrographic surgery does not make this assumption but displays the margins of the tissue for histological examination, and allows a primary tumour mass, growing in continuity to be excised completely with minimal loss of normal tissue. There are important lessons to be learned from the experiences of micrographic surgery in treating cutaneous SCC (see below).

Local metastases

Microscopic metastases may be found around high-risk primary cutaneous SCC. Under these circumstances a ‘wide’ surgical margin extending well beyond the primary tumour may include such metastases and thus have a higher cure rate than a narrower margin. Mohs’ micrographic surgery removes tumour growing in continuity but does not identify in-transit micrometastases. For this reason some practitioners of Mohs’ micrographic surgery will excise a further surgical margin when treating high risk tumours after the Mohs’ surgical wound has been histologically confirmed to be clear of the primary tumour mass.

Histological assessment of surgical margins

Conventional histological examination of one or more transverse sections of excised tissue displays a cross-section of the tumour and tissue margins. This is the best way of assessing and categorizing the nature of the tumour, and it is usual to comment on whether the tumour extends to the tissue margin, or if not, to record the margin of uninvolved skin around the tumour. The value of such comments depends on how closely the section examined reflects the excised tissue in general. If SCC appears to extend to the margin of the examined tissue, then it should be assumed, particularly if the true margin of the tissue has been stained prior to sectioning, that excision is incomplete. Orien- tating markers or sutures should be placed in the surgical specimen by the surgeon to allow the pathologist to report accurately on the location of any residual tumour. A pathologist, using the conventional ‘breadloaf’ technique for examining tissue, typically views only a small sample of the specimen microscopically, and this may allow incompletely excised high-risk tumour to go undetected. There are several alternative tissue preparations that allow the peripheral margins of the excised tissue to be more comprehensively examined. The clinician and pathologist must work closely together in order to ensure appropriate sampling and microscopic examination of excised tissue, particularly with high-risk tumours.

Mohs’ micrographic surgery

Mohs’ micrographic surgery allows precise definition and excision of primary tumour growing in continuity, and as such would be expected to reduce errors in
primary treatment that may arise due to clinically invisible tumour extension. There is good evidence that the incidence of local recurrent and metastatic disease are low after Mohs’ micrographic surgery and it should therefore be considered in the surgical treatment of high-risk SCC, particularly at difficult sites where wide surgical margins may be technically difficult to achieve without functional impairment.\textsuperscript{12,41} (Strength of Recommendation B, Quality of Evidence II-iii). The best cure rates for high risk SCCs are reported in series treated by Mohs’ micrographic surgery.\textsuperscript{41} Where Mohs’ micrographic surgery is indicated but not available then one of the other histological techniques to examine the peripheral margin of the excised tissue should be employed.\textsuperscript{60}

However, there are no prospective randomized studies comparing therapeutic outcome between conventional or wide surgical excision vs. Mohs’ micrographic surgery for cutaneous SCC.

It is firmly established that incomplete surgical excision is associated with a worse prognosis and, when doubt exists as to the adequacy of excision at the time of surgery, it is desirable, where practical, to delay or modify wound repair until complete tumour removal has been confirmed histologically.\textsuperscript{28,41–45,53}

Curettage and cautery

Excellent cure rates have been reported in several series\textsuperscript{41,63,74,78} and experience suggests that small (< 1 cm) well-differentiated, primary, slow-growing tumours arising on sun-exposed sites can be removed by experienced physicians with curettage. There are few published data relating outcome after curettage of larger tumours and different clinical tumour types.

The high cure rates reported following curettage and cautery of cutaneous SCC (Quality of Evidence II-iii) may reflect case selection, with a greater proportion of small tumours treated by curettage than by other techniques, but also raise the question as to whether curettage per se has a therapeutic advantage. The experienced clinician undertaking curettage can detect tumour tissue by its soft consistency and this may be of benefit in identifying invisible tumour extension and ensuring adequate treatment. Conventionally, cautery or electrosication is applied to the curetted wound and the curettage–cautery cycle then repeated once or twice. In principle, curettage could be combined with other treatments such as surgical excision, cryotherapy or radiotherapy; it is routinely undertaken to ‘debulk’ the tumour prior to Mohs’ micrographic surgery. Curettage provides poorly orientated material for histological examination and no histological assessment of the adequacy of treatment is possible. Curettage and cautery is not appropriate treatment for locally recurrent disease.

Cryosurgery

Good short-term cure rates have been reported for small histologically confirmed SCC treated by cryosurgery in experienced hands. Prior biopsy is necessary to establish the diagnosis histologically. There is great variability in the use of liquid nitrogen for cryotherapy and significant transatlantic variations in practice. For this reason caution should be exercised in the use of cryotherapy for SCC, although it may be an appropriate technique for selected cases in specialized centres.\textsuperscript{41,77} Cryosurgery is not appropriate for locally recurrent disease.

Radiotherapy

Radiation therapy alone offers reported short- and long-term cure rates for SCC that are comparable with other treatments.\textsuperscript{12,41,74} Radiotherapy will, in certain circumstances, give the best cosmetic and/or functional result. This will often be the case for lesions arising on the lip, nasal vestibule (and sometimes the outside of the nose) and ear, among others. Certain very advanced tumours, where surgical morbidity would be unacceptably high may also be best treated by radiotherapy.

Elective prophylactic lymph node dissection

Elective prophylactic lymph node dissection has been proposed for SCC on the lip greater than 6 mm in depth and cutaneous SCC greater than 8 mm in depth, but evidence for this is weak.\textsuperscript{46,49} (Strength of Recommendation C, Quality of Evidence II-iii). Elective lymph node dissection is not routinely practised and there is no compelling evidence of benefit over morbidity.\textsuperscript{29,30,36}

The multiprofessional oncology team

Patients with high risk SCC and those presenting with clinically involved lymph nodes should ideally be reviewed by a multiprofessional oncology team which includes a dermatologist, pathologist, appropriately
trained surgeon (usually a plastic or maxillofacial surgeon), clinical oncologist and a clinical nurse specialist in skin cancer. Some advanced tumours are not surgically resectable and these should be managed in a multiprofessional setting in order that other therapeutic options are considered. Patients should be provided with suitable written information concerning diagnosis, prognosis and follow-up support, local and national support organizations and, where appropriate, access to a multiprofessional palliative care team.

**Follow-up**

Early detection and treatment improves survival of patients with recurrent disease. Ninety-five percent of local recurrences and 95% of metastases are detected within 5 years. It would therefore seem reasonable for the patient who has had a high-risk SCC to be kept under observation for recurrent disease for this period of time (Strength of Recommendation A, Quality of Evidence II-ii). Patients should be, as far as possible, instructed in self-examination. Observation for recurrent disease may be undertaken by the specialist, primary care physician or by patient self-examination. The decision as to who follows the patient will depend upon the disease risk, local facilities and interests.

**Summary of treatment options for primary cutaneous squamous cell carcinoma**

Please see Table 1 for recommendations.

**Appendix 1**

Full details of the British Association of Dermatologists’ guidelines process are published in a previous edition of the journal.

Broders' histological classification of differentiation in squamous cell carcinoma

Broders devised a classification system in which grades 1, 2 and 3 denoted ratios of differentiated to undifferentiated cells of 3 : 1, 1 : 1 and 1 : 3, respectively. Grade 4 denoted tumour cells having no tendency towards differentiation.
